Abstract: Modulations of Immune Functions and Oxidative Status Induced by Noise Stress: Kui-Cheng ZHENG, et al. Department of Environmental and Preventive Medicine, Faculty of Medicine, University of the Ryukyus—Noise has long been realized as an environmental stress causing physiological, psychological and behavioral changes in humans. The aim of the present study was to determine the effect of acute or chronic noise stress on both cellular and humoral immune responses and oxidative status. BALB/c mice were exposed to 90 dB (A) white noise 5 h per day for either 3 d or 4 wk. Hormone levels, splenic lymphocyte proliferation, lymphocyte subsets in spleen and thymus, serum antibody and oxidative status were determined. A 3-d exposure to noise stress resulted in increased hormone levels, splenic lymphoproliferation and serum IgM. On the other hand, a 4-wk exposure to noise stress caused a reduction of splenic lymphoproliferation, splenic CD4+ cells and serum IgG, but hormone levels and urinary 8-hydroxy-2'deoxyguanosine (8-OHdG) were increased. These results imply that acute exposure to noise stress may enhance immune responses, whereas chronic exposure to noise stress may suppress both cellular and humoral immune functions. The effect of noise stress on immune functions may be related to neuroendocrine modulation and oxidative imbalance as well.

(J Occup Health 2007; 49: 32–38)

Key words: Noise stress, Cellular immune response, Humoral immune response, Neuroendocrine, Oxidative stress

Noise, an environmental stressor, has been known as a health risk not only for workers in a variety of occupations, but also for the general population. Along with rapid industrialization in many developing countries, noise exposure is on an increasing trend, both in industrial areas and general living areas. Evidence has shown that noise exposure may produce hearing loss, sleep disturbance and stress-related health effects such as annoyance, hypertension and ischemic heart disease1). A study performed in aircraft workers revealed that exposure to large pressure amplitude and low frequency noise resulted in a high prevalence of oropharynx infections of viral, bacterial and fungal origins2). A study carried out on animals indicated that noise exposure prolonged healing of surgical wounds made on rats’ backs3). These results imply a potential immunosuppressive effect of noise stress in humans and animals. However, generally the effect of noise stress on the immune system has not been well defined. Only a few animal models, particularly of the mouse and rat, have been used to explore the changes of the immune function after exposure to noise, but the results of these studies are not consistent. Moreover, most of these studies in animals have mainly targeted the cellular immune responses such as the absolute numbers of lymphocytes or leucocytes, lymphocyte activity or natural killer (NK) cell activity, and the evidence for changes of the humoral immune response caused by noise stress is very limited.

It has been known that environmental stress may cause oxidative DNA damage4). Oxidative stress has been reported to be an important factor in the cascade of cochlear events resulting from noise or medication induced sensorineural hearing loss5, 6). However, little is known about the interaction of oxidative stress and immune response in the pathogenesis of disorder induced by noise exposure.

The purpose of this study was to further investigate the effect of noise stress on both cellular and humoral immune responses, and on general oxidative damage.
To achieve this, immune functions and oxidative status were determined within the same animal.

**Materials and Methods**

**Animals**

Six-week-old male BALB/c mice, weighing 20–25 g, were used for the study. To avoid stress caused by isolation or overpopulation, each cage (30 × 36 × 16 cm) contained 2 or 3 mice. The mice were kept in a room under constant temperature (25 ± 2°C) and humidity (50–70%) with a 12-h light/dark cycle (light on from 07:00–18:00 h). They were allowed to adapt to our laboratory environment for 1 wk before the start of the experiment. Animal care was in compliance with applicable guidelines from the Ryukyu University Policy on Animal Care and Use.

**Noise exposure**

The white noise was produced by a noise generator (SF-05, Rion Company Ltd., Tokyo, Japan) and amplified by an amplifier which was connected to a loudspeaker. The sound intensity was measured using a sound level meter and maintained at about 90 dB (A). One group of 10 mice was exposed to noise 5 h (from 22:00 to 3:00 h) each day at the height of the diurnal activity cycle for 3 consecutive days, and another group of 10 mice were exposed to noise for 4 wk (28 d) with the same exposure protocol. Two control groups, each one with 10 mice, for both the 3-d and 4-wk noise exposure groups, were kept in a quiet room and only exposed to daily activity at 40–50 dB (A) of sound intensity.

**Determination of hormone levels**

On the 4th or the 29th day, blood was obtained from both exposed and control mice and serum was prepared and stored at −80°C for later analysis. The serum corticosteroid was measured using the fluorescence polarization immunoassay (FPIA)\(^7\). Plasma catecholamines, such as adrenaline and dopamine, were measured using a three-column system of high performance liquid chromatography (HPLC)\(^8\).

**Splenic lymphocyte proliferation assay**

Spleens were aseptically resected and a single-cell suspension was obtained by teasing the tissue through 50-mesh stainless steel wire screens into iced cold RPMI 1640. The cell suspension was treated with 0.1 mol/l Tris · HCl, pH 7.2, containing 8 g/l Tris ammonium chloride to lyse red blood cells. Spleen cells (5 × 10^5 cells per well) in complete RPMI 1640 containing 10% fetal bovine serum, 100 U/ml penicillin and 100 U/ml streptomycin were dispensed into 96-well flat-bottomed microtiter plates and cultured in triplicate for 30 h at 37°C in a humidified 5% CO\(_2\) incubator in the presence of 5 µg/ml concanavalin A (ConA) (Sigma, USA). Cells cultured without ConA served as a negative control. Lymphocyte blastogenic response was determined by the method of Hansen et al.\(^9\), which is a modification of the method of Mossman\(^10\). Briefly, 25 µl of 1 mg/ml 3-(4, 5-dimethyl-2-thiazoly)2, 5-diphenyl-2h-tetrazolium bromide (MTT) was added to each lymphocyte culture. After 1 h incubation, 100 µl of extraction buffer was added. After overnight incubation, the absorbance was measured at 570 nm. The mitogen response was calculated as the mitogen stimulation index.

**Lymphocyte subset analysis**

Single cell suspensions from thymus and spleen were prepared and lymphocyte subpopulations were identified by phenotypic analysis of surface markers. Briefly, 1 × 10^6 cells in PBS were stained with 10 µl of a mixture of labeled monoclonal antibodies (CD4 or CD8) at 4°C for 20 min in the dark. The cells were washed once with PBS and then filtrated through nylon mesh. The stained cells were analyzed for their fluorescence intensity by flow cytometry.

**Serum antibody determination**

Total serum IgM and IgG were determined using mouse

Mice were exposed to noise for 3 d or 4 wk. Values are expressed as means ± SD. Each group had 10 mice.

*Significantly different from control value at p<0.01; *Significantly different from control value at p<0.05.
IgM ELISA quantitation Kit (Bethyl Laboratories, Inc, TX, USA) and mouse IgG ELISA quantitation Kit (Bethyl Laboratories, Inc, TX, USA), respectively, according to the manufacturer’s instructions.

Oxidative stress analysis

Urine was collected and centrifuged. 8-hydroxy-2’-deoxyguanosine (8-OHdG) in urine was determined using the ELISA method with a New 8-OHdG Check Kit (Japan Institute for the Control of Aging, Shizuoka, Japan) according to the manufacturer’s instructions and adjusted against urinary creatinine. The limit of detection in urinary 8-OHdG is 0.5–200 ng/ml.

Statistical analysis

Statistical analysis of data was performed by using Student’s t-test. A value of \( p < 0.05 \) was considered significant.

Results

Blood hormone levels

As shown in Table 1, corticosteroid and adrenaline levels in control mice were 1.6 \( \mu g/dl \) and 723.8 pg/ml, respectively. Three days of exposure to noise stress resulted in a 2.5-fold increase of corticosteroid (5.58 \( \mu g/dl, p < 0.01 \)) and a 1.5-fold increase of adrenaline (1756.9 pg/ml, \( p < 0.01 \)). Dopamine concentrations between control and noise-exposed mice were not significantly different.

After 4 wk of exposure to noise, corticosteroid was increased from 2.08 to 4.25 \( \mu g/dl (p < 0.01) \) and adrenaline was increased from 792.8 to 954.9 pg/ml (\( p < 0.05 \)) as compared to the control, but dopamine was not significantly changed.

The weight gains in the same cage of mice before and after the experiment were not significantly different.

Lymphoproliferative responses

Figure 1 shows the splenic lymphoproliferative responses expressed as a stimulation index. After mice were exposed to noise stress for 3 d, splenic lymphoproliferation was significantly increased as compared to that in control mice (8.17 vs 9.99, \( p < 0.01 \)). However, after 4 wk of exposure, splenic lymphoproliferation was significantly decreased in exposed mice as compared to control mice (4.33 vs 7.27, \( p < 0.01 \)).

Lymphocyte subsets

As shown in Fig. 2, when mice were exposed to 3 d of noise, the percentage of CD4+ or CD8+ cells in the spleen was not significantly different from that in control mice. However, CD4+ cells in the spleen were significantly reduced after 4 wk of exposure, although CD8+ cells were not significantly changed between exposed and control

![Fig. 1. ConA-induced splenic lymphocyte proliferation (stimulation index) in control mice and noise-exposed (3 d or 4 wk of exposure) mice. Values are expressed as means ± SD. Each group has 10 mice.](image1)

![Fig. 2. The percentages of CD4+ and CD8+ cells in the spleen in control mice and noise-exposed (3 d or 4 wk of exposure) mice. Values are expressed as means ± SD. Each group has 10 mice.](image2)
Kui-Cheng Zhang, et al. Effect of Noise Stress on Immune Functions and Oxidative Status

Figure 3 shows the percentage of CD4$^+$ or CD8$^+$ cells in the thymus was not significantly different between exposed and control mice either after 3 d of exposure or after 4 wk of exposure.

**Serum antibodies**

Figure 4 shows the changes of serum IgM concentrations. A 3-day exposure to noise resulted in a significant increase of serum IgM as compared to control mice (25.4 ng/ml vs 14.4 ng/ml, $p<0.01$), whereas they were not significantly different between exposed and control mice after 4 wk exposure to noise (14.4 ng/ml vs 19.2 ng/ml, $p>0.05$).

As shown in Fig. 5, four weeks of exposure to noise caused a significant decrease of serum IgG in exposed mice as compared to control mice (22.1 ng/ml vs 57.3 ng/ml, $p<0.01$), although it was not significantly changed after 3 d of exposure (48.3 ng/ml vs 42.3 ng/ml, $p>0.05$).

**Oxidative stress**

Figure 6 shows urinary 8-OHdG concentrations in exposed and control mice. Although urinary 8-OHdG was not significantly different between exposed and control mice (20.1 ng/ml vs 18.3 ng/ml, $p>0.05$) after 3 days of noise exposure, it was significantly increased in exposed mice over that in control mice (44.2 ng/ml vs 24.9 ng/ml, $p<0.01$) after 4 wk of noise exposure.

**Discussion**

Due to the increasing trend of noise exposure in general living environments both in industrialized nations and in developing world regions, the pathogenesis resulting from noise stress needs to be well clarified. The present study
was undertaken to determine the effect on the immune function and oxidative status following a short period or a long period of noise stress. Our results show a 3-d exposure to noise resulted in the enhancement of immune responses expressed as the elevated ConA-induced splenic lymphoproliferative responses and serum IgM levels, whereas a 4-wk exposure to noise stress resulted in the suppression of immune functions manifested as reduced levels of lymphoproliferative responses and CD4+ cells in the spleen, and decreased serum IgG concentrations.

Exposure to aversive events or stressors affects various aspects of the immune function. It has been indicated that the innate non-specific immune response, as well as the specific immune response, may be altered by stress11, 12. However, the stress-induced effects may be variable depending on the type and characteristics of the stressor, the specific immune parameter under investigation, and the time passed between exposure to the stressor and monitoring of the immune function. Noise exposure has long been used as a stressor to investigate its effect on biological and biochemical responses. In a rat model exposed to 80 dB of rock music for 24 h, macrophage secretion of IL-1 and neutrophil release of O2− anion were reduced13. Another animal model in C57/BL6 mice showed that exposure to unpredictable 100 dB noise stress for 1 wk resulted in the reduction of both splenic Thy+ lymphocytes (indicator for T-lymphocytes) and Lyt-1.2+ lymphocytes (functionally similar to human T-helper cells)14. These 2 experiments showed a suppressive effect on cell-mediated immune function caused by acute noise stress. However, our data showed an enhancement effect on both cellular and humoral immune functions caused by 3 d of noise stress.

Our data also showed that 4 wk of exposure to noise stress caused suppression not only of cellular immune functions, but also of humoral function. These results are in agreement with the report by Aguas, et al.15. In their experiment, BALB/c mice exposed to low-frequency noise (≥90 dB, ≤500 Hz) for 8 months showed decreases in CD4+ and CD8+ T splenic lymphocytes and in IgM+ B lymphocytes. Furthermore, they also reported that a long term (2,184 cumulative hours) exposure to low-frequency noise could suppress the normal immune response to bacterial infection in Wistar rats16. On the other hand, the report by Lange et al. showed that 4 wk of exposure to 100 dB noise in C57/BL6 mice did not change splenic Thy+ lymphocytes and Lyt-1.2+ lymphocytes17. Moreover, Monjan and Collector demonstrated in their study that 4 or 5 wk of exposure to 120 dB noise enhanced T-cell activity in mice18. The limited contradictory results of the above studies do not allow a consistent interpretation of the effect of noise stress on the immune function. The discrepancy among our results and the results previously reported by other researchers might be due to the difference of animal species, sound intensity, exposure duration or animal handling applied in the experiment. In addition, it might be that noise stress has variable effects on the different immune parameters monitored in the studies. The study performed on Wistar rats exposed to intermittent noise (85 dB) for different period (24 h, 7 d and 21 d) indicated that various parameters of the immune function are affected differentially over time in a period of chronic noise stress, possibly due to sequential activation of different physiological mechanisms19.

Noise stress has been found to induce neuroendocrine effects in humans and animals8, 19–21. It has been revealed that corticotropin-releasing hormone is released during stress and stimulates the release of adenocorticotropic hormone21, which in turn releases corticosterone from the adrenal cortex. Elevation of the corticosterone level accelerates the generation of free radicals22 and suppresses the immune function23. However, in the present study, although corticosteroid and adrenaline levels were significantly increased after 3 d as well as after 4 wk of noise stress, the noise-induced modulation of the immune response was not consistent between these two different exposure periods. This might imply that besides hormones, other factors or mechanisms may also account for the effect of noise stress on the immune response.

Oxygen free radicals can cause a variety of damage to DNA, including DNA single and double strand breaks, base modifications and abasic sites24–26, and they are thought to be involved in the mechanisms of aging and in carcinogenesis and other disorders27, 28. Recent evidence has shown that stress can alter hormonal levels, lymphocyte subsets and the production of reactive oxygen species29. In a rat model reported by Srikumar et al., noise stress significantly increased the lipid peroxidation with concomitant depletion of antioxidants, but significantly suppressed the cell-mediated immune response30. Free radical imbalance in the hippocampus and medial prefrontal cortex has been documented to be related with spatial memory error caused by chronic noise stress in the rat40. To investigate oxidative status caused by noise stress, 8-OHdG was determined in the present study. 8-OHdG, a DNA base-modified product31 generated by reactive oxygen species, is mutation prone32 and has been shown to be a good marker of oxidative damage33. Therefore, the formation of 8-OHdG in DNA and its urinary excretion have been frequently measured to assess oxidative stress in humans. Our results for urinary 8-OHdG show that oxidative stress was significantly increased following 4 wk of noise exposure. The increased oxidative stress might partially account for the suppression of the cellular and humoral immune functions caused by noise exposure in our study.

In conclusion, the results of the present study indicate
that short-term exposure to noise stress may enhance the immune function, whereas long-term exposure may result in suppression of the cellular and humoral immune responses. The mechanisms underlying noise-induced reduction of the immune function may be related not only to neuroendocrine change, but also to the imbalance of oxidative stress.
